Defining whether medical therapy is effective in women with deep rectovaginal endometriosis and in which circumstances it can be considered an alternative to surgery is important for patients and physicians. Numerous observational and some randomized controlled studies demonstrated that different hormonal drugs improved pain and other symptoms in approximately two-thirds of women with deep rectovaginal endometriosis. Because major differences in the effect size of various compounds were not observed, much importance should be given to safety, tolerability, and cost of medications when counseling patients. Progestins seem to offer the best therapeutic balance when long-term treatments are planned. Women should be informed that hormonal drugs control but do not cure endometriosis and that, to avoid surgery, they should be used for years. Medical therapy is not an alternative to surgery in women with hydronephrosis, severe subocclusive bowel symptoms, and in those wishing a natural conception. A progestin should systematically be chosen as a comparator in future randomized trials on novel medications for deep endometriosis. In the meantime, the use of existing drugs should be optimized, and medical and surgical treatments could be viewed as subsequent stages of a stepwise approach. In general, there is no absolute “best” choice, and women must be thoroughly informed of potential benefits, potential harms, and costs of different therapeutic options and allowed to choose what they deem is better for them. (*Fertil Steril*® 2017;108:913–30. ©2017 by American Society for Reproductive Medicine.)

**Key Words:** Dysmenorrhea, dyspareunia, endometriosis, medical therapy, pelvic pain

*Medical therapy [for rectovaginal and colorectal endometriosis] has been found to be ineffective or temporary, with a rate of recurrence as high as 76%, whereas surgical excision is effective in relieving pain.*

Minelli et al. (1)

*One of the main characteristics of symptoms related to deeply infiltrating endometriosis lesions is*

*that they dramatically respond to therapeutic amenorrhea.*

Fauconnier et al. (2)

In high-ranking medical journals, renowned experts convey opposite messages regarding medical treatment of deep endometriosis. The above are just but 2 examples depicting the ongoing dispute on radical surgery vs. hormonal therapy for this condition. According to Pellicer and Zupi (3),

“...excellent speakers have promoted the efficacy of hormone treatments without knowing the benefits of surgical approaches; talented surgeons are explaining the benefits of a radical removal of lesions without any experience with the medical treatment options.”

Definitively disentangling this issue is difficult and, owing to the dearth of comparative effectiveness research in the specific field of deep endometriosis, even international guidelines may not be of great help. Thus, investigators perpetuate this disagreement, with potentially detrimental consequences in terms of patients' confusion and physicians' uncertainty.

Given this background, our aim was to critically appraise and summarize the available evidence on the effects of hormonal treatments in women with deep rectovaginal endometriosis, and to provide factual information to be

used when counseling patients and making shared medical decisions in different clinical scenarios. A PubMed search has been conducted for the period 2000 to 2017 using combinations of the medical subject terms “deep endometriosis,” “retrovaginal endometriosis,” “pelvic pain,” and “medical treatment.” Only articles reporting original data on hormonal therapy for deep endometriosis, written in English, and published in peer-reviewed journals were selected.

We believe that medical therapy should be considered as the first-line treatment in women with symptomatic deep endometriosis not seeking natural conception. At the same time, we inform readers that in our referral center the knowledge and experience is available to treat different deep endometriosis forms also surgically (4–7).

## HISTOLOGIC AND BIOLOGICAL BASIS OF MEDICAL THERAPY FOR DEEP ENDOMETRIOSIS

A vast body of evidence support the notion that endometriosis is primarily a peritoneal disease (8–12). If this is true, the so called “deep infiltrating endometriosis” is one manifestation of a complex disease with a single pathogenic mechanism (i.e., retrograde menstruation; see, as reviews, references [13–15]). However, as discussed by Gordts et al. in the present issue of this journal (16), other theories may explain the pathogenesis of deep endometriosis, such as the metaplasia or müllerian rests theory.

If deep endometriosis originates from superficial endometriosis (i.e., organ infiltration starts from the serosal layer) (17), it should respond to hormonal manipulation similarly to peritoneal implants. However, compared with superficial peritoneal endometriosis, deep endometriosis has a distinct histologic characteristic: in addition to the ectopic endometrial-like mucosa (endometrial epithelium and stroma) and the fibrotic component deriving from inflammation (caused by the metabolic activity of the ectopic endometrium and possibly also by repeated micro-hemorrhages), smooth muscle fibers are also present. This is expected because the so-called deep endometriosis infiltrates the wall of hollow viscera such as the bowel, the bladder, the ureter, and the vagina. The result is a sort of desmoplastic lesion in the form of nodules or plaques comprising the three constituents: mucosal, fibrotic, and smooth muscular (18).

In a baboon model, induced deep endometriotic nodules were larger and more invasive when grafting specimens containing the junctional zone (19). Along the invasion front, increased mitotic activity, fewer adhesion molecules (20), and higher nerve fiber density were observed (21). The progressively increasing density with time suggests a potential role of nerve fibers in the development of deep endometriotic lesions (22).

If the smooth muscular component is the histologic hallmark of deep endometriosis (18), we consider as “deep” those forms of endometriosis that infiltrate at least the muscular layer of the considered abdomino-pelvic organs and agree with Koninckx et al. (14), who suggest abandoning the old criterion according to which an endometriotic lesion should be defined deep when it infiltrates at least 5 mm of tissue

beneath the peritoneum (23). This arbitrary definition rapidly gained popularity and has been used, untested, for decades. However, it is unclear whether and how this degree of depth has been systematically and precisely measured in all the studies in which it has been adopted. Moreover, it is unknown to what extent this measurement is reproducible, because interobserver agreement is undetermined but potentially low. With the advent of accurate imaging techniques, identifying the endometriotic infiltration of the muscular layer of different hollow organs is feasible (17,24–28). This criterion seems valid, reliable, and reproducible, and it has been adopted by several authors when conducting studies on medical treatment of deep endometriosis (29–32).

Hormonal treatments should thus exert an effect on two of the three components of deep endometriosis, that is, the ectopic endometrial mucosa and the smooth muscle fibers infiltrated by it. On the other hand, a major effect of medical therapies on the fibrotic component seems unlikely, although an influence of progestins on fibrosis remodeling during time cannot be excluded, owing to their demonstrated anti-inflammatory properties (33–37).

On the basis of these premises, medical treatment for deep endometriosis may constitute a therapeutic alternative when established fibrotic stenosis of hollow viscera, such as ureteral infiltration with hydronephrosis and intestinal infiltration with occlusive symptoms, are excluded (14, 17, 38). Bowel occlusion is likely when wall infiltration is associated with fixed, sharp angulation, or when the lumen is intrinsically narrow, such as in cases of involvement of the last ileal loop and the ileocecal valve (39). However, infiltration of the rectal ampulla and the posterior vaginal fornix may cause severe symptoms but almost never constitute a surgical emergency (6).

Two pathogenic mechanisms explain pain associated with deep endometriotic lesions: chronic inflammation deriving from the metabolic activity of ectopic endometrium, and secondary fibrosis with embedding of endometriotic glands into scar tissue. Persisting ectopic micro-hemorrhages despite fibrotic burial lead to typical bluish nodules formation and initiate a sort of desmoplastic reaction causing firm adhesion and immobilization of adjacent organs and ligaments (6, 40).

Recurring release of mediators of inflammation, such as prostaglandins and cytokines, may cause a functional-type, mostly cyclic pain, such as catamenial pseudo-cystitis and irritative intestinal symptoms, whereas pressure on nodules and plaques and traction of inelastic tissues and immobilized pelvic structures generates an organic type of pain, such as deep dyspareunia. The two types of pain may coexist, as in cases of catamenial dyschezia.

In addition, a downstream effect of inflammation is neurotrophism with local neo-neurogenesis and activation of sensory nerve fibers, as recently observed also in the experimental baboon model (22). This may cause hyperalgesia, the occurrence of excruciating pain when a nonpainful stimulus is applied (41). Indeed, women with deep endometriosis generally experience major exacerbation of pain when even minor pressure is exerted on nodules or indurated lesions (41, 42). A painful sensation that is out of proportion with the intensity of nociceptor stimulation is characteristic of

neuropathic pain, which is usually related to nerve injury or inflammatory stimuli (42–44).

Tyrosine kinase receptor B and the mu-opioid receptor transcription, induced by proinflammatory cytokines synthesized and released by activated macrophages and mast cells in deep endometriotic lesions, is decreased by GnRH agonist and progestin treatment (45), whereas previous use of combined oral contraceptives (OCs) or progestins was associated with a significant reduction in the expression of nerve growth factor and of small sensory nerve fiber density (46).

Moreover, several lines of evidence support the notion that oxidative stress in the pelvic cavity is pivotal for both endometriosis development and adhesion formation (see, as a review, Donnez et al. [47]). In particular, an excess of erythrocytes regurgitated in the pelvis during menstrual reflux would overcome the phagocytic capacity of peritoneal macrophages. This would result in extracellular release of hemoglobin, heme, and catalytic iron, with formation of reactive oxygen species and consequent cytotoxic and genotoxic effects (47). Medical treatments inducing amenorrhea or a major reduction in the amount of uterine bleeding would abolish or greatly limit retrograde menstruation, thus decreasing the release of prooxidant and proinflammatory factors (48).

Therefore, a rationale exists for the use of hormonal therapy to treat both inflammatory pain and secondary neo-neurogenesis and hyperalgesia. However, confusion seems to be present in the literature regarding the main objective of medical therapy. In fact, the usual recurrence of symptoms at variable times after drug withdrawal is still used as a demonstration that hormonal treatments are ineffective because they do not definitively cure deep endometriosis (1). This vision does not take into account two facts. First, hormonal treatments can suppress but not eradicate ectopic endometrium definitively. Second, in general medical treatments control but rarely cure chronic disorders, whether of metabolic (e.g., diabetes), immune (e.g., autoimmune disorders), inflammatory (e.g. Crohn's disease and ulcerative colitis), or unknown (e.g., essential hypertension) origin. Therefore, medical treatments for deep endometriosis should be considered no less and no more than other treatments for several chronic medical conditions. The practical issue here is defining when medical therapy is advantageous over surgery, taking into consideration that, if chosen, hormonal treatments should be continued until a pregnancy is desired or the physiologic menopause ensues. This may mean many years of treatment, and this important aspect must be clarified during counseling, together with the fact that conservative surgery as an isolated measure does not guarantee definitive symptom relief. The real choice is often not between medical or surgical treatment but between medical treatment alone and surgical treatment followed by postoperative medical treatment (49).

## MEDICAL THERAPY FOR DOUGLAS POUCH AND DEEP RECTOVAGINAL ENDOMETRIOSIS

### Premise

An endometriotic lesion has been defined as vaginal “when lesions infiltrate the anterior rectovaginal pouch, posterior

vaginal fornix and retroperitoneal area between the anterior rectovaginal pouch and posterior vaginal fornix” (12). In other words, rectovaginal endometriosis is a deep lesion that concurrently infiltrates the anterior rectal and the posterior vaginal walls (Fig. 1). A nodule located in the posterouterine pouch that does not infiltrate the vaginal and rectal walls should be categorized as a Douglas pouch lesion and not as rectovaginal endometriosis.

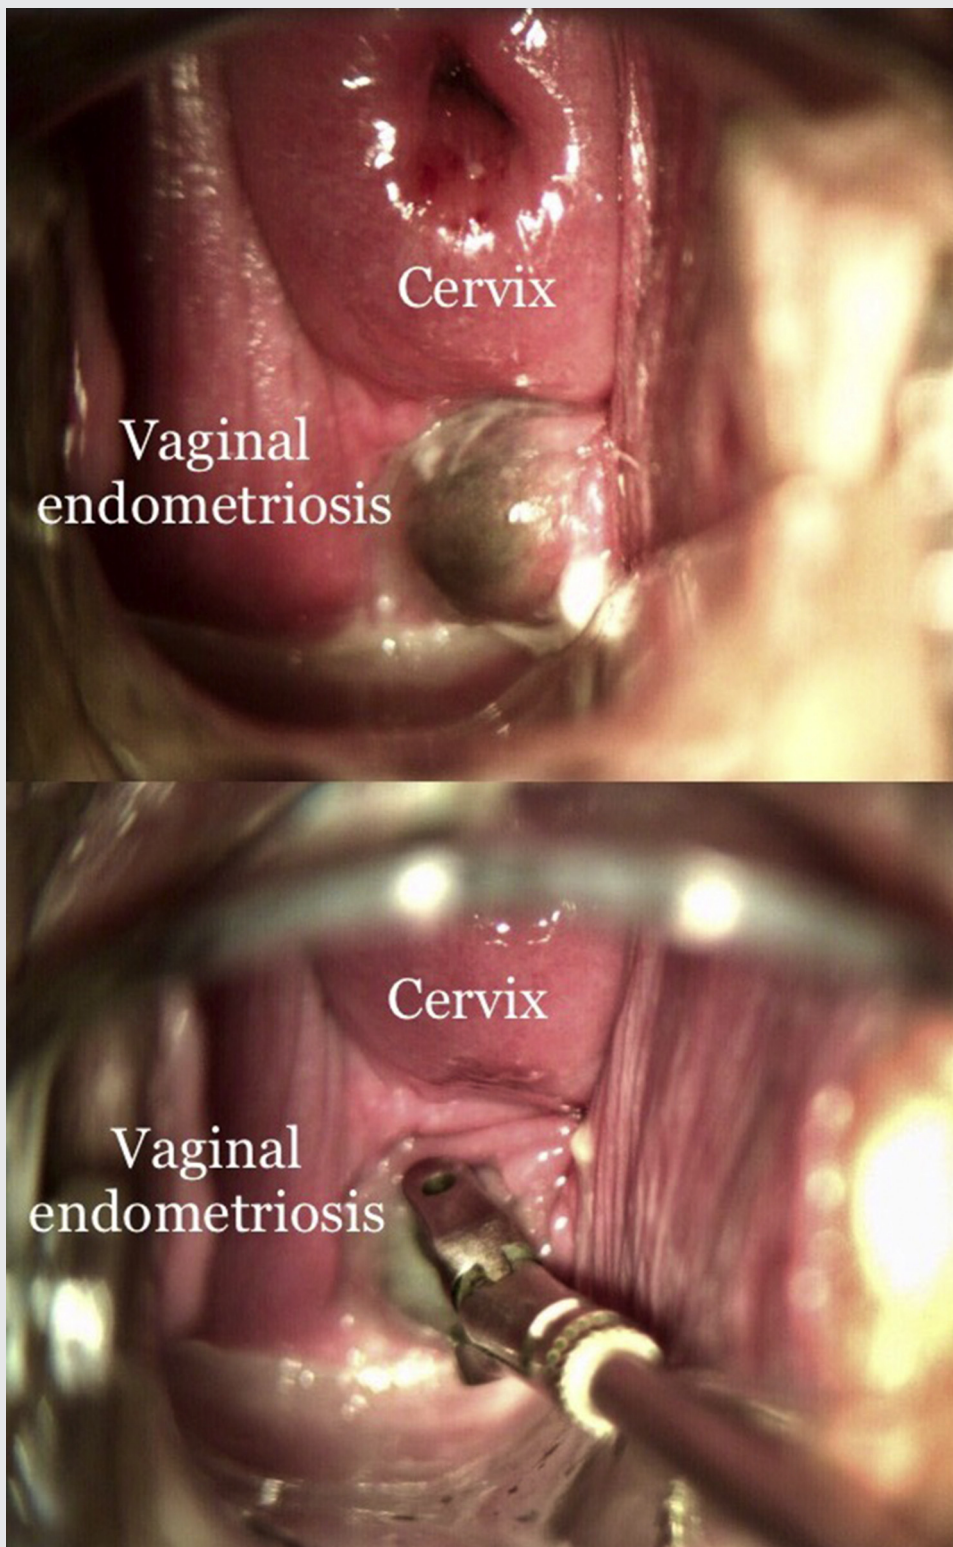

Responsiveness of the endometrium within deep lesions to gonadal steroids is the prerequisite for medical therapy aimed at inducing metabolic quiescence of ectopic glands. The presence of estrogen and P receptors in peritoneal and ovarian endometriotic lesions was demonstrated by Nisolle et al. several years ago (50, 51). Those investigators also suggested the concept of P resistance (50, 51). More recently, Noël et al. (52) demonstrated that estrogen and P receptors were present in major histologic components of rectovaginal, bladder, and uterosacral endometriosis, including the smooth muscle fibers. Progesterone receptors were also present in endometriosis of the colon (52). Ferrero et al. (53) evaluated the changes in the dimension of rectovaginal endometriotic nodules during 12-month treatment with OCs, progestins, or triptorelin plus tibolone. The volume of the nodules decreased progressively at 6- and 12-month evaluation in three out of four of the 83 women studied, without statistically significant differences between subgroups of patients using different drugs.

Dysmenorrhea is the most frequent symptom also in women with rectovaginal endometriosis, but hormonal treatments that induce amenorrhea relieve menstrual pain by definition. Apart from dysmenorrhea, the complaints characteristically associated with vaginal and rectal endometriosis are, respectively, deep dyspareunia and dyschezia (40,54–56). Both symptoms are caused by pressure on fibrotic (inextensible) lesions, during deep-thrust penetration in the former case and passage of hard stools in the latter case. These organic-type pains are usually exacerbated by intra- and peri-lesional inflammatory phenomena occurring during and shortly after menstruation. Medical therapies should exert an appreciable effect on inflammatory and neuropathic pain. The effect on organic pain, likely associated with modifications in the volume of lesions, may be limited by the amount of intra- and peri-lesional fibrosis.

The results of treatment with various hormonal therapies have been reported in 10 noncomparative studies published between 2000 and 2017, in which a total of 258 patients with rectovaginal endometriotic lesions were recruited. In the same time period nine comparative studies were published, including a total of 778 participants. Two studies were randomized controlled trials (RCTs), five were patient preference trials, one was a cohort study, and one a before-and-after study. The main characteristics of all the identified studies are shown in Tables 1 and 2, where complete lists of adverse events associated with the use of the various medications are included. More detailed information on selected studies is provided below.

## Estrogen–progestins and Progestins

In the first RCT conducted specifically on women with highly symptomatic rectovaginal endometriosis, a monophasic estrogen–progestin combination (ethinyl E<sub>2</sub> 0.01 mg plus cyproterone acetate 3 mg) and norethindrone acetate (NETA; 2.5 mg/d), both used continuously for 12 months, were compared (65). According to an intention-to-treat analysis 28 of 45 participants (62%) in the estrogen–progestin combination group and 33 of 45 (73%) in the NETA group were satisfied with the treatment received. All pain symptoms, including deep dyspareunia and dyschezia, were substantially reduced by both medications. Between-group differences in satisfaction with treatment and pain relief were not statistically different.

In a patient preference trial, Ferrero et al. (66) compared the same dose of NETA (2.5 mg/d) combined with letrozole (2.5 mg/d; n = 41) with NETA used as monotherapy (2.5 mg/d; n = 41). The combined therapy relieved nonmenstrual pain and deep dyspareunia to a greater extent compared with NETA alone, but interestingly, the satisfaction with treatment at the end of 6 months of therapy was similar (56% vs. 63%, respectively) because of the higher incidence of adverse effects observed in the former group. As expected, pain symptoms recurred after drug discontinuation, without between-group differences.

In another patient preference trial (7), NETA (2.5 mg/d for 12 months) was compared with laparoscopic surgery in women specifically selected because of severe deep dyspareunia; 59 of 154 participants had rectovaginal endometriosis. At the 12-month intention-to-treat evaluation of these women, 54% (13 of 24) of those who chose surgery were satisfied with the treatment received, compared with 51% (18 of 35) of those who chose NETA. In the former group a marked and rapid short-term improvement in dyspareunia was observed, followed by partial pain recurrence. The effect of NETA on pain at intercourse was more gradual but progressive throughout the study period (7). Variations in sexual functioning, psychological status, and health-related quality of life followed substantially similar patterns (73).

Desogestrel (75 µg/d per os) was evaluated in two patient preference studies. Leone Roberti Maggiore et al. (70) compared this progestin with an estrogen–progestin vaginal ring used continuously in 143 women. After 12 months of treatment, 62% of participants who chose desogestrel were satisfied with their treatment, compared with 36% of those who chose the vaginal ring. The same research group (71) compared the effect of desogestrel (n = 62) and that of a low-dose monophasic OCP used cyclically (n = 82) in women suffering from migraine without aura. Less frequent and severe migraine attacks were observed in progestin users with respect to OCP users. At the 6-month evaluation, a higher degree of patient satisfaction was observed in the former group (61%) compared with latter (38%).

The effect of dienogest (2 mg/d) was compared with that of NETA (2.5 mg/d) in a 12-month before-and-after study (72). A total of 64 out of 180 women had rectovaginal endometriosis. At intention-to-treat analysis in this subgroup, 67% of patients who used NETA were satisfied with the

treatment received, compared with 68% of those who used dienogest. The latter progestin was better tolerated, but several women discontinued it because of cost. Because dienogest is much more expensive than NETA, the authors concluded that it should not be considered as the first medical approach.

Morotti et al. (63) prescribed dienogest in 25 women with persistent pain associated with rectovaginal endometriosis despite NETA therapy. After treatment for 6 months, pain symptoms significantly decreased and sexual functioning and health-related quality of life improved. Given the study design adopted, a placebo effect cannot be excluded, because the rationale for such diverse effects of same-class compounds is unclear. In addition, the long-term effectiveness of NETA has been confirmed in a retrospective cohort study conducted by this research group on 103 patients with symptomatic rectovaginal endometriosis and followed for 5 years (64). A total of 16 women discontinued the progestin because of adverse effects. Overall, 69% of participants who completed the study (corresponding to 41% of the patients originally enrolled) were satisfied with their long-term NETA treatment. Deep dyspareunia and dyschezia improved substantially already at the 1-year evaluation. Unexpectedly, the volume of the recto-vaginal nodule increased in 7 patients despite NETA treatment.

Two noncomparative studies confirmed the efficacy of dienogest in improving pain symptoms in women with rectovaginal endometriosis (31, 32).

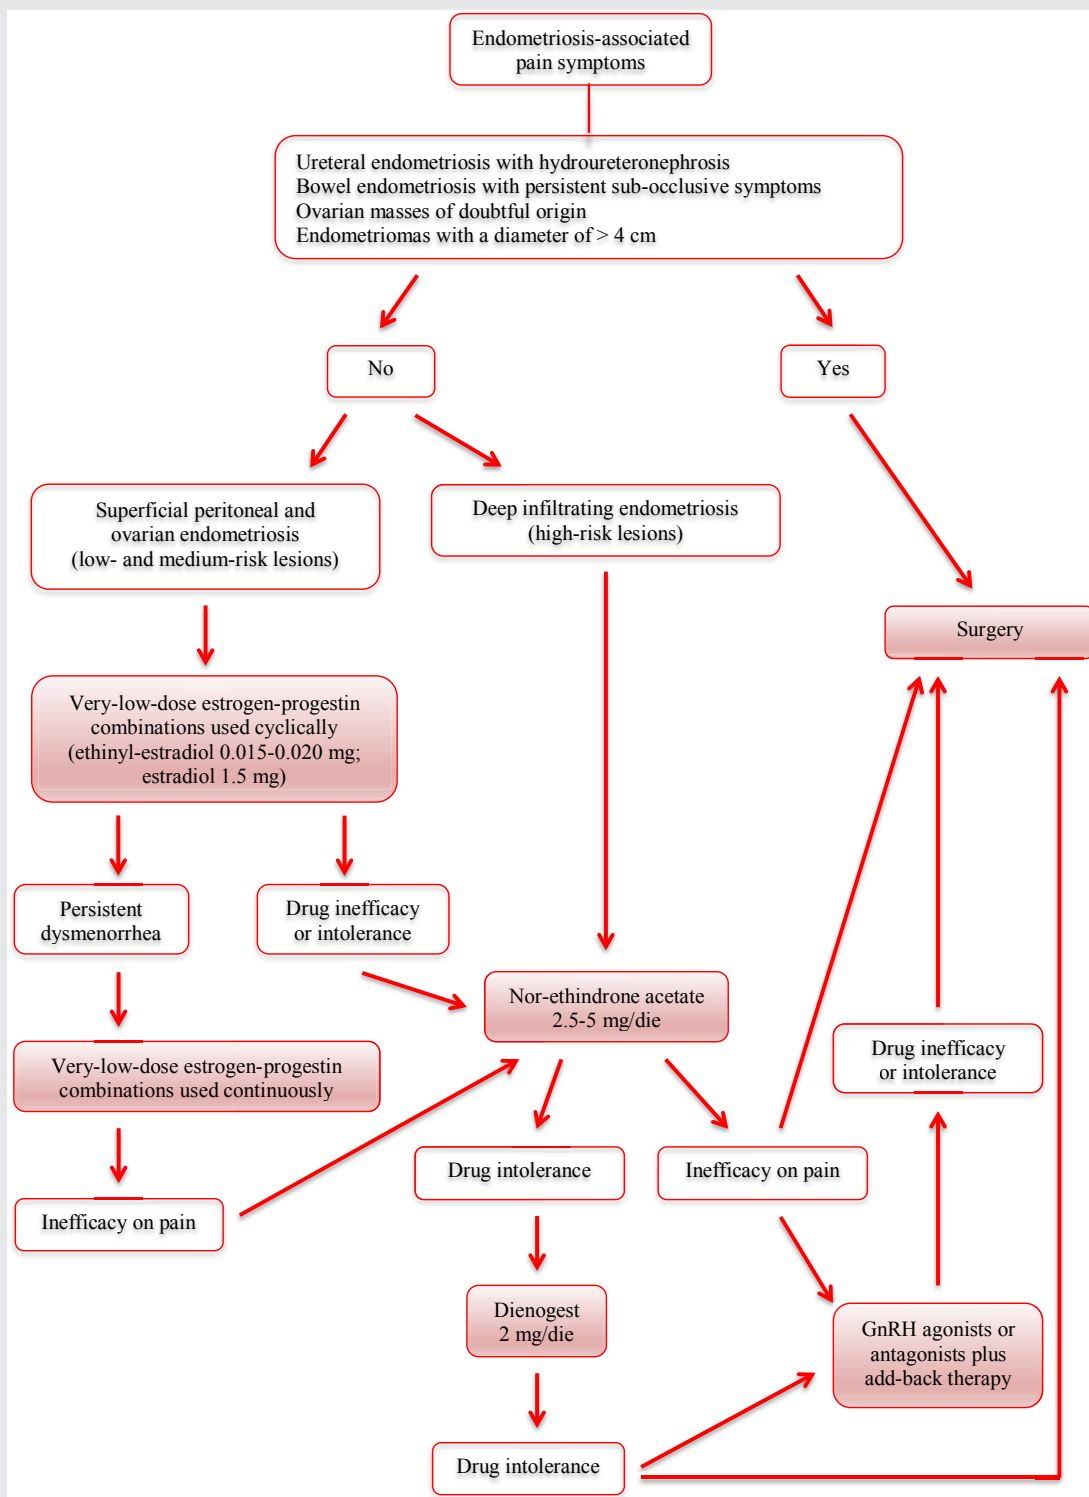

The use of the levonorgestrel-releasing intrauterine device (LNG-IUD) for 1 year has been assessed by Fedele et al. (58) in 11 patients. At baseline, moderate to severe dysmenorrhea was referred by all women, and deep dyspareunia by eight. At the end of treatment, dysmenorrhea was completely relieved and mild dyspareunia was present in five participants. The volume of the rectovaginal lesion, as assessed at vaginal ultrasonography, decreased progressively through the study period. However, a series of patients studied by Ferrero et al. did not respond to the LNG-IUD and required further medical therapy (62).

In particular, the effect of LNG-IUD on deep dyspareunia is less definite than that on dysmenorrhea and is probably limited (74, 75). In addition, the LNG-IUD does not inhibit ovulation, thus it does not seem effective in preventing endometrioma development or recurrence (75).

## Danazol

Danazol was used per vaginam in two prospective noncomparative studies. Razzi et al. (60) treated 21 women with rectovaginal endometriosis with danazol, 200 mg/d for 12 months. Dysmenorrhea, dyspareunia, dyschezia, and pelvic pain disappeared after 6 months of treatment, and the effect persisted until the end of the study period. The volume of rectovaginal plaques decreased from a mean baseline value of 3.1 mL to 1.2 mL at 1-year assessment. Four women complained of vaginal irritation during the first month of therapy. All the participants experienced regular menstruations throughout the entire period of observation. This mandates the use of barrier contraception when this treatment modality is chosen.

FIGURE 2

Suggested algorithm for individualized treatment of endometriosis-associated pain by means of a lesion-based, three-tiered risk stratification system and a stepwise pharmacologic approach (81) in women not seeking conception and preferring medical therapy rather than surgery.

Vercellini. Medical therapy for deep endometriosis. Fertil Steril 2017.

Ferrero et al. (62) used a lower dose of danazol (100 mg/d) for 6 months in 15 women with pain persisting after insertion of the LNG-IUD. Symptom intensity improved progressively and significantly during the study period, and 12 of 15 women were satisfied with their treatment at 6-month evaluation. The rectovaginal nodule volume decreased from 2.3 mL at baseline to 1.7 mL at the end of treatment. Adverse effects were minimal and well tolerated.

### GnRH Agonists

A GnRH agonist for the treatment of rectovaginal endometriosis has been used in a single, noncomparative, prospective study (57). A total of 15 patients used leuporelide acetate in a monthly 3.75-mg depot formulation for 6 months. Two women dropped out of the study because of inefficacy of medical therapy and requested surgery. The remaining 13 patients showed a marked improvement in moderate to severe pain symptoms, which, however, recurred soon after drug discontinuation. Apparently on the basis of the study hypothesis of a curative effect of GnRH agonist treatment, the authors maintained that the failure rate of this treatment modality (request for further treatment) was 87% (13 of 15).

### GnRH Antagonists

Gonadotropin-releasing hormone antagonists prevent binding of endogenous GnRH to its pituitary receptors, which are not down-regulated. Thus, titrating GnRH antagonists dosage allows modulation of inhibition of ovarian  $E_2$  synthesis (48). Several phase 1 and 2 trials have already been conducted on GnRH antagonists, and the results of two phase 3 explanatory trials have recently been published demonstrating the dose-dependent superiority of elagolix, an oral, nonpeptide, GnRH antagonist, over placebo in reducing endometriosis-associated dysmenorrhea and nonmenstrual pain (76). The former finding is expected by definition whenever a drug induces amenorrhea or hypomenorrhea. Unfortunately, the reduction in bone mineral density also was dose-dependent (77). Some other GnRH antagonists are currently under evaluation (48).

However, the concrete advantages of GnRH antagonists over GnRH agonists have yet to be determined. In fact, the “flare-up” effect induced by GnRH agonists can be greatly limited administering the drugs during the luteal phase, whereas choosing a daily oral administration vs. a monthly or 3-monthly depot administration is a matter of personal preference. No data focusing specifically on the effect of GnRH antagonists on deep rectovaginal endometriosis are available yet. However, there is no reason to believe that they should work less than other available medications. Moreover, GnRH antagonists appear well tolerated (77).

There are several issues to be clarified here, including whether these new drugs can be used alone or necessitate add-back therapies anyway, as with GnRH agonists, to prevent bone demineralization; whether they can safely be used for long periods; and whether their effectiveness and cost-effectiveness, evaluated by means of pragmatic trials, will be comparable or superior to that of progestins. In other words, the goals will be [1] investigating whether the effect observed under the highly controlled conditions typical of explanatory

trials will be maintained also when these drugs will be provided to unselected patients under usual circumstances of healthcare practice; and [2] defining the “efficiency” of GnRH antagonists for the treatment of endometriosis, that is, the effect of these compounds in relation to the resources they consume (78).

### Aromatase Inhibitors

Ferrero et al. (69) conducted an RCT on the use of oral letrozole (2.5 mg/d) in 35 women with symptomatic rectovaginal endometriosis (69). The aromatase inhibitor was combined with NETA (2.5 mg/d;  $n = 17$ ) or triptorelin (depot 11.25 mg/3 mo;  $n = 18$ ) to prevent ovarian stimulation. After 6 months of therapy, 65% of women in the former group were satisfied with their treatment, compared with 22% in the latter group. No significant between-group difference was observed in pain relief. Treatment discontinuation because of adverse effects was rare in the progestin group ( $n = 1$ ) but frequent in the GnRH agonist group ( $n = 8$ ). This study does not provide evidence that aromatase inhibitors work because, when hormonal medications are combined, it is not possible to discriminate the specific effect of each compound. On the other hand, aromatase inhibitors are ineffective if not associated with other drugs that inhibit ovulation.

### Comment

Abundant evidence from RCTs and observational studies demonstrates the benefits of hormonal treatments in patients with symptomatic rectovaginal endometriosis. Overall, information on more than 1,000 women who used hormonal medications for rectovaginal endometriotic lesions is available. This appears as an interesting body of data on which to base clinical understanding and medical decision making. Importantly, the degree of satisfaction with treatment has been reported in most studies. This is a patient-reported outcome that summarizes the global woman's experience with her therapy, including pain relief, side effects, variations in health-related quality of life, psychological status, and sexual satisfaction, as well as cost issues. Approximately two-thirds of patients with symptomatic rectovaginal endometriosis were satisfied with progestin treatments at intention-to-treat analyses.

However, some inconsistencies are difficult to explain. In particular, despite statistically significant reductions in pain at intercourse as measured with validated scales, only moderate improvements in general sexual function were observed during medical therapies (7, 73, 79). This emphasizes the notion that female sexual functioning is multifactorial and that impacting on a single, although important, aspect of sexual life may not affect substantially the overall sexual experience (79, 80). Of relevance here, the same limitations pertain also to surgical treatment (7, 73, 79), and collaborating with a sex therapist with experience in endometriosis patients may be advisable for those women who complain of persistent sexual dysfunction despite considerable reduction in pain at intercourse (80).

Additionally, dyschezia was substantially relieved in most patients during hormonal treatments. However, defecation pain usually does not have emotional implications comparable to those associated with dyspareunia and rarely

constitutes the sole indication for surgery. Thus, medical therapy seems as the ideal approach in women who refer this symptom as their main complaint.

## DISCUSSION: PROMISES, PROMISES

Deep infiltrating endometriosis is the really severe endometriotic disease. From a therapeutic point of view, and independently of different pathogenic hypotheses, clinicians and patients should know whether and to what extent medical treatments are effective when infiltrating lesions are present, in which circumstances they can be used, and whether they really constitute an acceptable alternative to surgery.

In general, hormonal drugs (or combinations of hormonal drugs) were demonstrated effective in relieving pain and other associated symptoms in most women with Douglas pouch and rectovaginal endometriosis. Discriminating the specific effect of medications on deep lesions from that on superficial and ovarian ones is practically impossible, because the various histologic phenotypes generally coexist. However, improvements in deep dyspareunia, dyschezia, and several intestinal complaints strongly suggest a specific effect of medical therapies on infiltrating endometriosis, because a robust association between symptom type and deep lesion site has been demonstrated (12, 56).

It is difficult to precisely define the effect size of each compound, also because very few randomized, comparative effectiveness trials have been conducted selectively in patients with deep endometriosis. Overall, it does not seem that major differences exist between different medications. Therefore, much value should be given to aspects such as safety, tolerability, and cost, because medical therapies, being symptomatic and not curative, may be needed for years. In this regard, low-dose, monophasic OCPs and progestins seem to constitute the best available compromise between all the above factors and should be proposed as the first-line medical treatment.

In general, very-low-dose, monophasic OCPs may be suggested for peritoneal and ovarian endometriosis, whereas NETA and dienogest should be preferred for rectovaginal lesions. Adding aromatase inhibitors did not improve efficacy to a great extent but increased the incidence of adverse events and raised costs. The combination of GnRH agonists and add-back therapies was demonstrated to be consistently effective in reducing pain and alleviating symptoms associated with infiltrating endometriosis and could be considered as a second-line, long-term option in highly selected women at greatly increased surgical risk. Otherwise, conservative or definitive surgery should be carefully evaluated as a suitable and less costly alternative.

Recently Casper (37) maintained that “both norethindrone acetate and dienogest have regulatory approval for treating endometriosis and may be better than OCPs as a first-line therapy [of endometriosis].” On the basis of the available evidence (81), we are uncertain whether this should systematically apply also to patients with superficial peritoneal and ovarian forms, because the former women usually respond to low-dose, monophasic OCPs used cyclically or continuously, and the latter women benefit from anovulation, however obtained (82–85). Treatment with progestins alone

for years may impact on the serum lipid profile and on bone mineral content, although a causal relation between these surrogate markers and cardiovascular events and pathologic fractures, in general, should not be taken for granted (86). On the other hand, women with infiltrating endometriosis are affected by the disease form associated with the most severe pain symptoms, with the most potentially serious clinical consequences, and with the riskiest procedures in case surgery is performed. Therefore, we concur that it seems wise here to accept minor metabolic effects, with the objective of avoiding the estrogenic stimulation of deep lesions and obtaining more profound disease quiescence.

We have recently proposed a lesion-based, three-tiered risk stratification system (low-, intermediate-, and high-risk group) for an individualized management of women with, respectively, superficial peritoneal, ovarian, and infiltrating endometriosis forms (81). According to this risk strata system, patients with deep infiltrating lesions should be considered a high-risk group and, when not seeking pregnancy, should use progestins instead of OCPs as a first-line medical therapy. Moreover, the contraposition between medical and surgical treatment should be overcome by applying a stepwise approach, whereby surgery should be considered when progestins are not effective or not tolerated (Fig. 2). In this regard, we fully agree with Abrao et al. (17) when they conclude, “In women with deep endometriosis, surgery is the therapy of choice for symptomatic patients when deep lesions do not improve with a medical treatment.”

It has also been recently stated that, because currently used medical therapies merely control but do not cure endometriosis, “those women who do not respond to existing therapies may benefit from new therapies with different mechanisms of action. [...] There remains an unmet clinical need among women with endometriosis for a specific disease-modifying therapy to provide long-term symptom relief that persists after the treatment period” (87). Although this is undoubtedly the best imaginable future scenario for all women with endometriosis, we also deem that the clinical research conducted in the past years does not seem to support such an optimistic view (87–90). The rationale for a curative effect of novel drugs is unclear, because they should exert selective cytotoxicity toward specific, autologous, benign cells. A careful balance should also be made considering adverse events and overall drug toxicity, because endometriosis is not a cancer. Of relevance here, RCTs on novel compounds for deep endometriosis should include a progestin as a standard comparator, because women should know whether new drugs are better than those they currently use. It is unfortunate that most RCTs sponsored by pharmaceutical industries have mainly registration purposes, are designed to systematically favor the experimental compound, rarely include objectives that matter to patients, and are selectively reported (88–93).

In the meantime, we should first learn how to optimize the medical treatment of women with deep endometriosis with drugs available now, because there is already abundant and consistent evidence that approximately two-thirds of patients can be safely and successfully managed for indefinite periods. This does not seem a discouraging achievement, and

suggesting surgery for deep endometriosis on the basis of the presupposition that medical treatments are ineffective, nowadays seems deceptive. In addition, existing compounds may be used differently. As an example, the vaginal route may reveal advantageous for administering medications in women with rectovaginal lesions. This understudied modality merits further development (67,94–96). Undeniably, several issues remain unsolved, and the need for therapy discontinuation when seeking a conception is among the most important ones. Moreover, it is well known that medical therapy has no role in endometriosis-associated infertility, because it does not enhance the likelihood of conception.

Beyond debates over “old” and “novel” drugs, or medical vs. surgical treatment, complete and detailed quantitative information on potential benefits, potential harms, and costs of therapeutic alternatives remains pivotal in the management of women with deep endometriosis. What may be difficult for us clinicians to accept is the fact that we should no longer decide for our patients (97). We may suggest considering important variables that patients may not expect or not even know (e.g., the potential complications of unoperated deep bowel endometriosis during pregnancy or when undergoing IVF) (98) and guide them through the shared medical decision-making process, but the woman should eventually choose, as it is the woman who might experience the side effects of medications for years or suffer the consequences of surgery in case of complications. With due exceptions, there is no absolute best choice: different women may choose differently according to their preferences and priorities.
